Time-changed Linear Quadratic Regulators

Andrew Lamperski and Noah J. Cowan

Abstract—Many control methods implicitly depend on the assumption that time is accurately known. For example, the finite-horizon linear quadratic regulator is a linear policy with time-varying gains. Such policies may be infeasible for controllers without accurate clocks, such as the motor systems in humans and other animals, since gains would be applied at incorrect times. Little appears to be known, however, about control with imperfect timing. This paper gives a solution to the linear quadratic regulator problem in which the state is perfectly known, but the controller’s measure of time is a stochastic process derived from a strictly increasing Lévy process. The optimal controller is linear and can be computed from a generalization of the classical Riccati differential equation.

I. INTRODUCTION

This paper studies the finite-horizon linear quadratic regulator (LQR) with temporal uncertainty. Solutions to finite-horizon optimal control problems are typically time-varying feedback policies. Implicitly, it is assumed that the controller has perfect knowledge of time, even in cases of imperfect state information. This paper examines the consequences of assuming that controller’s measure of time is stochastic.

A stochastic process can be time-changed by replacing its time index, objective time, by a monotonically increasing stochastic process, subjective time [1]. Time-changed stochastic processes arise in finance, since changing the time index to a measure of economically relevant events, such as trades, can improve modeling [2]–[4]. This new time index is, however, stochastic with respect to calendar time.

Similar notions of objective time and subjective time arise in the study of time estimation in the nervous system. Human timing is subject to neural and environmental perturbation [5]. Furthermore, humans rationally exploit the statistics of their temporal noise during simple timed movements, such as button pushing [6] and pointing [7]. To analyze more complex movements, a theory of feedback controllers that compensate for temporal noise is desirable.

The study of control systems with temporal uncertainty is, however, relatively unexplored. Attention has been devoted to the problem of clock synchronization in distributed systems [8], [9]. Less effort has been devoted studying the impact of asynchronous clock behavior on common control issues, such as stability [10] and optimal performance [11]. Only a limited amount of work focuses on general consequences of temporal uncertainty for control [12], [13].

This paper focuses on the linear quadratic regulator problem with perfect state information, but a stochastically time-changed control process. The optimal cost-to-go function is derived by dynamic programming, based on a generalization of the classical LQR Riccati differential equation. The results apply to a wide class of stochastic time changes given by strictly increasing Lévy processes.

Section II reviews the classical linear quadratic regulator, and demonstrates how temporal uncertainty can lead to poor behavior. Next, in Section III, basic ideas from Lévy processes are reviewed, and the class of temporal noise models is defined. The problem of interest and its solution are stated in Section IV, while the solution is derived in Section V. Finally, a conclusion is given in Section VI.

II. CLASSICAL LQR AND TIME

The classical linear quadratic regulator chooses inputs $u_t = g_t(x_t)$ that minimize the quadratic integral

$$\int_0^{t_f} (x_t^T Q x_t + u_t^T R u_t) \, dt + x_{t_f}^T \Phi x_{t_f},$$

subject to linear dynamics

$$\dot{x}_t = A x_t + B u_t$$

and initial condition $x_0 = x$. Here $Q$ and $\Phi$ are positive semidefinite, while $R$ is positive definite.

The optimal solution is given by

$$u_t = L_t x_t,$$  \hspace{1cm} (1)

where

$$L_t = -R^{-1} B^T P_t,$$  \hspace{1cm} (2)

and $P_t$ satisfies the backward differential equation

$$-\dot{P}_t = Q + A^T P_t + P_t A - P_t B R^{-1} B^T P_t,$$  \hspace{1cm} (3)

with final condition $P_{t_f} = \Phi$.

The linear quadratic regulator requires perfect knowledge of the state and, perhaps more subtly, perfect knowledge of time. While linear quadratic control with imperfect state information is commonly studied, little seems to be known about optimal control with imperfect time information. The following example shows that using the standard LQR policy with noisy time measurement can lead to poor behavior.

Example 1: Consider the system defined by the state matrices

$$A = \begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix}, \quad B = \begin{bmatrix} 0 \\ 1 \end{bmatrix},$$

with cost matrices given by $\Phi = I$, $Q = 0$, and $R = 1$. 

A. Lamperski is with the Department of Engineering, University of Cambridge, UK a.lamperski@eng.cam.ac.uk 
N. J. Cowan is with the Department of Mechanical Engineering, Johns Hopkins University, USA ncowan@jhu.edu
Now say that instead of knowing time \( t \), the controller only has access to a noisy measure of time is given by

\[
\zeta_t = \sup\{s + B_s : 0 \leq s \leq t\},
\]

where \( B_t \) is the standard unit Brownian motion. The process, \( \zeta_t \), can be interpreted as a noisy clock. A realization of \( \zeta_t \) is plotted in Figure 2(b), cf. Example 4.

Figure 1 shows the result of using the policy

\[
u(\zeta_t, x_t) = L_{\zeta_t} x_t
\]

over the time horizon \( \{t : \zeta_t \in [0, t_f]\} \). Intuitively, the controller uses \( \zeta_t \) as though it were the correct clock reading, but this can result in a suboptimal gain when \( \zeta_t \neq t \). Note that the time horizon varies with the realization of \( \zeta_t \).

For some choices of \( A, B, Q, R, \) and \( \Phi \), the policy, (5), can perform arbitrarily worse than (1).

This paper generalizes (1), (2), and (3) in order to optimally compensate for uncertainty generated from a relatively large class of temporal noise models.

III. LÉVY PROCESSES AND TIME CHANGES

This section presents the class of temporal noise models used in this paper. Two notions of time are used: subjective time and objective time. Subjective time is modeled as a stochastic process parametrized by objective time. The noisy clock process from (4) is an example of a subjective time model.

A. Background on Lévy Processes

Basic notions from Lévy processes required to define the general class of subjective time models are now reviewed. The definitions and results can be found in [14].

A real-valued stochastic process \( X_t \) is called a Lévy process if

- \( X_0 = 0 \) almost surely (a.s.).
- \( X_t \) has independent, stationary increments: If \( 0 \leq s < t \), then \( X_s \) and \( X_t - X_s \) are independent and \( X_t - X_s \) has the same distribution as \( X_{t-s} \).
- \( X_t \) is stochastically continuous: For all \( a > 0 \) and all \( s \geq 0 \), \( \lim_{t \to s} P(|X_t - X_s| > a) = 0 \).

It will be assumed that Lévy processes in this paper are right-continuous with left-sided limits, i.e. they are càdlàg. No generality is lost since, for every Lévy process, \( X_t \), there is a càdlàg Lévy process, \( \tilde{X}_t \), such that \( \tilde{X}_t = X_t \) for almost all \( t \).

A monotonically increasing Lévy process is called a subordinator. The following theorem, adapted from [14], implies that every subordinator can be uniquely characterized by a function on \( \mathbb{C} \).

**Theorem 1:** Let \( X_t \) be a subordinator. There exists a unique complex-valued function \( \psi \), called the Laplace exponent of \( X_t \), such that for all \( z \in \mathbb{C} \) with \( \text{Re } z > 0 \), \( \psi \) is analytic at \( z \) and

\[
E[e^{-zX_t}] = e^{-t\psi(z)}.
\]

The function, \( \psi \), is called the Laplace exponent because (6) is the Laplace transform of the distribution of \( X_t \). A converse to Theorem 1 holds, but constraints on the form of \( \psi \) are required. Equation (6) is derived from the famous Lévy-Khintchine formula for Lévy processes.

So far, the discussion in this section has been completely standard. This paper will employ (6) for the less common task of computing expectations of matrix exponentials, \( E[e^{AX_t}] \), where \( X_t \) is a subordinator. To reason about unstable \( A \), the definition of the Laplace exponent must be extended, when possible, to values of \( z \) with \( \text{Re } z \leq 0 \).

Recall that \( \psi \) is always analytic at \( z \) with \( \text{Re } z > 0 \). It could, however, be analytic on a larger region. Define \( r_{\text{min}} \in [-\infty, 0) \) to be the minimal value \( r \) such that \( \psi \) is analytic at all \( z \) with \( \text{Re } z > r \) and define the domain of \( \psi \), \( \text{dom}(\psi) \), as

\[
\text{dom}(\psi) = \{z \in \mathbb{C} : \text{Re } z > r_{\text{min}}\}.
\]

It can be shown that (6) holds on all of \( \text{dom}(\psi) \).

**Example 2:** The simplest non-trivial subordinator is the Poisson process \( N_t \), which is characterized by

\[
P(N_t = k) = e^{-\gamma t} (\gamma t)^k \frac{k!}{k!},
\]

where \( \gamma > 0 \) is called the rate constant. Its Laplace exponent is given by \( \psi(z) = \gamma - \gamma e^{-z} \), which is found by computing the expected value directly. It follows that \( r_{\text{min}} = -\infty \) and \( \text{dom}(\psi) = \mathbb{C} \).

B. Subjective Time Models

Let \( \tau_s \) be a strictly increasing subordinator. In other words, if \( s < s' \) then \( \tau_s < \tau_{s'} \) a.s. (Note that any subordinator can be made to be strictly increasing by adding a drift term \( bs \) with \( b > 0 \).) The process \( \tau_s \) will have the interpretation of being the amount of objective time that has passed over \( s \) units of subjective time. The process \( \zeta_t \) will be an inverse
process that describes how much subjective time has passed over \( t \) units of objective time. Formally, \( \zeta_t \) is defined by
\[
\zeta_t = \inf \{ \sigma : \tau_\sigma \geq t \}.
\]
Note that \( \zeta_{\tau_\sigma} = s \) a.s. Indeed, \( \zeta_{\tau_\sigma} = \inf \{ \sigma : \tau_\sigma = \tau_s \} \), by definition. Since \( \tau_\sigma \) is right continuous and strictly increasing, a.s., it follows that \( \zeta_{\tau_\sigma} = s \), a.s.

**Example 3:** The case of no temporal uncertainty corresponds to \( \tau_\sigma = s \) and \( \zeta_t = t \). The Laplace exponent of \( \tau_\sigma \) is computed directly as \( \psi(z) = z \) and \( \text{dom}(\psi) = \mathbb{C} \).

**Example 4:** A more interesting temporal noise model is the inverse Gaussian subordinator. Fix \( \gamma > 0 \) and \( \delta > 0 \). Let \( C_t = \gamma t + B_t \), where \( B_t \) is a standard unit Brownian motion. The inverse Gaussian subordinator is given by
\[
\tau_s = \inf \{ t : C_t = \delta s \},
\]
with Laplace exponent \( \psi(z) = \delta(\sqrt{\gamma^2 + 2z} - \gamma) \). Here \( \text{dom}(\psi) \) corresponds to \( \text{Re} z > -\gamma^2/2 \). Derivation of \( \psi \), in this case, relies on techniques outside the scope of this paper. See [14].

It can be shown that the inverse process is given by
\[
\zeta_t = \sup \left\{ \delta^{-1} C_\sigma : 0 \leq \sigma \leq t \right\}.
\]
See Figure 2. Note that when \( \gamma = \delta = 1 \), the subjective time \( \zeta_t \) becomes the noisy clock process, (4).

In the preceding example, the process \( \tau_s \) has jumps, but the inverse, \( \zeta_t \), is continuous. The next proposition generalizes this observation for any strictly increasing subordinator, \( \tau_s \).

**Proposition 1:** The process \( \zeta_t \) is continuous almost surely.

**Proof:** Fix \( \epsilon > 0 \) and \( t \geq 0 \). Set \( s = \zeta_t \). Strict monotonicity of \( \tau_s \) implies that \( \tau_{\max\{s-\epsilon,0\},\tau_{s+\epsilon}} \) is a nonempty interval, a.s. The inverse property of \( \zeta_t \) implies (almost surely) that \( t \in \tau_{\max\{s-\epsilon,0\},\tau_{s+\epsilon}} \) and \( \zeta_t \in \tau_{\max\{s-\epsilon,0\},\tau_{s+\epsilon}} \) for all \( t' \in \tau_{\max\{s-\epsilon,0\},\tau_{s+\epsilon}} \).

IV. Problem Statement and Main Result

Consider a linear system of the form
\[
y_t = Ay_t + Bu(\zeta_t).
\]
This system describes a scenario in which dynamics of a physical plant are described by motion in objective time, but the agent choosing \( u \) cannot directly measure time, but instead must rely on its subjective measure \( \zeta_t \).

Let \( x_s = y_{\tau_s} \) be the time-changed process. Note that (8) can be solved as
\[
y_t = e^{At} y_0 + e^{At} \int_0^t e^{-A\sigma} Bu(\zeta_\sigma) d\sigma.
\]
It follows that \( x_s \) can be computed as
\[
x_s = e^{A\tau_s} x_0 + e^{A\tau_s} \int_0^{\tau_s} e^{-A\sigma} Bu(\zeta_\sigma) d\sigma.
\]
Note that \( x_s \) depends on the values of \( u(r) \) for \( r \in [0,s] \). For compactness, \( u(r) \) will often be written as \( u_r \). Let

\[
\mathcal{F} = \{ \mathcal{F}_s \}_{s \geq 0}
\]
be the natural filtration associated with \( x_s \). A control policy is said to be admissible if \( u_s \) is measurable in \( \mathcal{F}_s \) and right-continuous with left limits.

Let \([0,S]\) be a finite interval of subjective time. The time-changed linear quadratic regulator is the admissible control policy that minimizes the expected quadratic cost
\[
\mathbb{E} \left[ \int_0^S \left( x_s^T Q x_s + u_s^T R u_s \right) ds + x_S^T \Phi x_S \right].
\]
Here it is assumed that \( Q \) and \( \Phi \) are positive semidefinite, while \( R \) is positive definite.

Given a policy \( u_s \), the expected cost-to-go is defined as
\[
J_s(x) = \mathbb{E} \left[ \int_s^S \left( x_r^T Q x_r + u_r^T R u_r \right) dr + x_S^T \Phi x_S \bigg| x_s = x \right].
\]
It follows that the regulator problem involves choosing the policy that minimizes \( J_0(x) \).

The solution to the time-changed regulator problem uses a Riccati-like differential equation whose terms depend on
the linear mappings described in the following lemma. The lemma is proved in Section V-B.

**Lemma 1:** If the all eigenvalues of $-2A$ lie in $\text{dom}(\psi)$, (7), then there are linear mappings, $F$, $G$, and $H$ such that
\[
\mathbb{E}[e^{AT\tau_s}Ye^{A\tau_s}] = Y + sF(Y) + O(s^2)
\]
\[
\mathbb{E}[e^{AT\tau_s}Ye^{A\tau_s}] = sG(Y) + O(s^2)
\]
\[
\mathbb{E}[\int_{0}^{\tau_s} e^{A\sigma} d\sigma Y \int_{0}^{\tau_s} e^{A\rho} d\rho] = sH(Y) + O(s^2).
\]

The eigenvalue assumption is made so that the equation
\[
\mathbb{E}[e^{(\lambda_1+\lambda_2)\tau_s}] = e^{-s\psi(-\lambda_1-\lambda_2)}
\]
holds whenever $\lambda_1$ and $\lambda_2$ are eigenvalues of $A$. Note that if $A$ is Hurwitz, then the eigenvalue requirement always holds.

**Example 5:** With no temporal noise, the mappings reduce to
\[
F(Y) = A^T Y + Y A, \quad G(Y) = Y, \quad H(Y) = 0. \quad (11)
\]
Furthermore, since $\psi$ is analytic everywhere, these formulas are true for any state matrix, $A$.

**Example 6:** Consider an arbitrary strictly increasing subordinator with Laplace exponent $\psi$. Let $A = \lambda$ where $\lambda$ is a real, non-zero scalar with $-2\lambda \in \text{dom}(\psi)$. Combining (6) with the formula $\int_{t}^{\tau_s} e^{\lambda s} ds = \lambda^{-1} e^{\lambda t} - 1$ shows that
\[
\mathbb{E}[e^{\lambda \tau_s} e^{A\tau_s}] = e^{-s\psi(-2\lambda)}
\]
\[
\mathbb{E}[e^{\lambda \tau_s} \int_{0}^{\tau_s} e^{A\sigma} d\sigma] = \lambda^{-1} (e^{-s\psi(-2\lambda)} - e^{-s\psi(-\lambda)})
\]
\[
\mathbb{E}[\int_{0}^{\tau_s} e^{A\sigma} d\sigma \int_{0}^{\tau_s} e^{A\rho} d\rho] = \lambda^{-2} (e^{-s\psi(-2\lambda)} - 2e^{-s\psi(-\lambda)} + 1).
\]

It follows that
\[
F(Y) = -\psi(-2\lambda) Y
\]
\[
G(Y) = \lambda^{-1}(\psi(-\lambda) - \psi(-2\lambda)) Y
\]
\[
H(Y) = \lambda^{-2}(2\psi(-\lambda) - \psi(-2\lambda)) Y.
\]

Applying similar ideas to state matrices in Jordan form, Lemma 1 can be viewed as a generalization of this example.

With all the required definitions now given, the main theorem of the paper can be stated. The theorem is proved in Section V.

**Theorem 2:** Let $\tau_s$ be a strictly increasing subordinator with Laplace exponent $\psi$. Assume that the eigenvalues of $-2A$ are contained in $\text{dom}(\psi)$ and $0 \in \text{dom}(\psi)$. The optimal expected cost-to-go is of the form $J_s(x) = x^T Y_s x$, where $Y_s$ solves the backward differential equation
\[
-\frac{d}{ds} Y_s = Q + F(Y_s) - G(Y_s) B (R + B^T H(Y_s) B)^{-1} B^T G(Y_s) T,
\]
with final condition $Y_S = \Phi$. The optimal policy is given by
\[
u_s = K_s x_s,
\]
where the gain $K_s$ is defined by
\[
K_s = -(R + B^T H(Y_s) B)^{-1} B^T G(Y_s) T.
\]

The optimal controller compensates for the temporal uncertainty, since the mappings $F$, $G$, and $H$, from Lemma 1, depend on the distribution of $\tau_s$. Thus, different subjective time models will lead to different optimal controllers.

**Example 7:** With no temporal noise, by plugging in the matrices from (11), the gain and cost-to-go reduce to (2) and (3), respectively. Thus, the time-changed linear quadratic regulator generalizes the classical linear quadratic regulator.

The following theorem is useful for comparing the expected costs for different linear policies. It will not be proved, since the main ideas of its derivation are contained in the proof of Theorem 2.

**Theorem 3:** If the control input is a linear policy, $u_s = L_s x_s$, then the expected cost-to-go is given by $J_s(x) = x^T P_s x_s$, where $P_s$ satisfies the backward differential equation
\[
-\frac{d}{ds} P_s = Q + F(P_s) + L_s^T B^T G(P_s) T + G(P_s) B L_s + L_s^T (R + B^T H(P_s) B) L_s,
\]
with final condition $P_S = \Phi$.

Note that the optimal gain, (13), is recovered by taking the derivative of (14) with respect to $L_s$ and setting to 0. Theorem 2 is not simply a special case of Theorem 3, however, since it gives the optimal input over all $\mathcal{F}_s$-measurable càdlàg policies. Theorem 3, on the other hand, assumes a-priori that the policy is linear.

**Example 8:** Consider the unstable scalar system described by $A = 1/6$ and $B = 1$ and cost matrices $Q = R = \Phi = 1$. Say that $\tau_s$ is the inverse Gaussian subordinator with $\gamma = \delta = 1$. Figure 3 compares the controller from Theorem 2 with the classical LQR controller.

**V. PROOF OF MAIN RESULT**

The proof of Theorem 2 is a continuous-time stochastic dynamic programming argument. As in the well-known case of differential equations driven by Brownian motion [16], the Hamilton-Jacobi-Bellman equation must be modified from the deterministic case, based on the the behavior of the stochastic process. In this paper, the required corrections are captured by Lemma 1. The dynamic programming argument is given in Subsection V-A and Lemma 1 is proved in V-B.

**A. Regulator Derivation**

The optimal expected cost-to-go is the minimum of (10) over all admissible policies. As in standard dynamic programming arguments [17], the optimal cost-to-go function is
As expected, the to-go that arises when the classical LQR gains, (2), are substituted into (14). Derived from the identity controller induces a large jump near trajectory $x_P$. The green line shows $\delta > 0$ sufficiently small,

$$x_{s+\delta} = e^{A(T_{s+\delta} - T_s)}x_s + \int_{T_s}^{T_{s+\delta}} e^{A(T_{s+\delta} - \sigma)}Bu\,d\sigma$$  \hspace{1cm} (17)$$

Furthermore, the second term on the right can be written as $\int_0^{T_{s+\delta} - T_s} e^{A\sigma}Bud\sigma$.

Let $\hat{\tau}_s$ be an independent realization of the process $\tau_s$. Define the noisy state matrices $A_\delta$ and $B_\delta$ by

$$A_\delta = e^{A\hat{\tau}_s}, \quad B_\delta = \int_0^{\hat{\tau}_s} e^{A\sigma}d\sigma B.$$  \hspace{1cm} (18)$$

Since $\tau_{s+\delta} - \tau_s$ and $\hat{\tau}_s$ have the same distribution, it follows that

$$x_{s+\delta} = A_\delta x_s + B_\delta u + O(\hat{\tau}_s \epsilon),$$  \hspace{1cm} (19)$$

where $d$ means that the two sides have the same distribution. Furthermore, $A_\delta$, $B_\delta$, and the $O(\hat{\tau}_s \epsilon)$ term are independent of $F_s$.

Since $x_s$ and $u_s$ are right-continuous, the integral in (15) can be approximated simply:

$$\int_s^{s+\delta} (x^T Qx_r + u^T R u_r) \, dr = \delta (x^T Qx + u^T R u) + O(\epsilon \delta).$$  \hspace{1cm} (20)$$

With the local approximations defined, the cost-to-go can now be derived. Note that $J_S(x) = x^T \Phi x$, so define $Y_S = \Phi$. For $s + \delta \leq S$, assume inductively that $J_{s+\delta}(x) = x^T Y_{s+\delta} x + O(\epsilon \delta)$ for some positive semidefinite matrix $Y_{s+\delta}$. Combining (15), (19), and (20) gives

$$J_s(x) = \min_u \left( \int_s^{s+\delta} (x^T Qx_r + u^T R u_r) \, dr + J_{s+\delta}(x_{s+\delta}) \right)$$

for small $\delta > 0$. Similar to (9), $x_{s+\delta}$ can be written as

$$x_{s+\delta} = e^{A(T_{s+\delta} - \tau_s)}x_s + \int_{\tau_s}^{T_{s+\delta}} e^{A(T_{s+\delta} - \sigma)}Bu(\sigma)d\sigma.$$  \hspace{1cm} (16)$$

Recall that $\tau_s$ and $u_s$ were assumed to be right-continuous. Furthermore $\zeta_\tau$ is continuous by Proposition 1. It follows that $x_{s+\delta} \rightarrow x_s$ as $\delta \downarrow 0$. Thus $x_s$ is right-continuous.

Fix $\epsilon > 0$ and assume that $x_s = x$ and $u_s = u$ (where $x$ and $u$ are simply vectors, not processes). By the inverse property, $u(\zeta_{\tau_s}) = u_s = u$ almost surely. Right-continuity of $u_s$ and $\zeta_\tau$ implies that for $\delta > 0$

$$x_{s+\delta} = e^{A(T_{s+\delta} - \tau_s)}x_s + \int_{\tau_s}^{T_{s+\delta}} e^{A(T_{s+\delta} - \sigma)}Bu(\sigma)d\sigma.$$  \hspace{1cm} (17)$$

Furthermore, the second term on the right can be written as

$$\int_0^{T_{s+\delta} - \tau_s} e^{A\sigma}Bu(\sigma)d\sigma.$$
Note that since \( Y_{s+\delta} \) is positive semidefinite, it follows from the form in Lemma 1 that \( H(Y_{s+\delta}) \) is also positive semidefinite. Similarly, \( R + B^T H(Y_{s+\delta}) B \) is positive definite. Thus, the unique minimizing input is given by \( u = K_{s+\delta} x \), with \( K_{s+\delta} \) given in (13). Plugging in the optimal input shows that \( J_s(x) = x^T Y_s x + O(\delta) \), where \( Y_s \) is the positive semidefinite matrix defined by
\[
Y_s = Y_{s+\delta} + \delta(Q + F(Y_{s+\delta})) - \delta G(Y_{s+\delta})B(R + B^T H(Y_{s+\delta})B)^{-1} B^T G(Y_{s+\delta})T.
\]

Letting \( \epsilon \) and \( \delta \) go to zero shows that \( J_s(x) = x^T Y_s x \), where \( Y_s \) solves the backward differential equation (12). 

B. Proof of Lemma 1

Assume that the Jordan decomposition of \( A \) has \( q \) blocks, and for each eigenvalue \( \lambda_i \), the corresponding Jordan block has size \( M_i \times M_i \). The matrix exponential can be written as
\[
e^{At} = \sum_{i=1}^{q} e^{\lambda_i t} \sum_{j=0}^{M_i-1} \frac{t^j \Gamma_i^j}{j!},
\]
for some matrices \( \Gamma_i^j \in \mathbb{C}^{n \times n} \) such that \( \sum_{j=1}^{q} \Gamma_i^j = I \). Thus,
\[
e^{AT} Y e^{At} = \sum_{i,j=1}^{q} \sum_{k=0}^{M_i-1} \sum_{l=0}^{M_j-1} t^{k+l} \Gamma_i^k \Gamma_j^l Y \Gamma_i^l Y \Gamma_j^l. \tag{23}
\]

Set \( \mu = \lambda_i + \lambda_j \). By hypothesis, \( -\mu \notin \text{dom}(\psi) \), and thus \( \psi \) is analytic at \( -\mu \). The desired expected value can be computed in terms of the scalars \( \mathbb{E} \left[ \tau_{\lambda} e^{\mu \tau} \right] \). For simpler algebra, set \( \beta(z) = -\psi(-z) \). Then from (6), \( \mathbb{E} [e^{\mu \tau}] = e^{-\psi(-\mu)} = e^{s \beta(\mu)} \). Now \( \mathbb{E} \left[ \tau_{\lambda} e^{\mu \tau} \right] \) can be computed as
\[
\mathbb{E} [\tau_{\lambda} e^{\mu \tau}] = \frac{d^k}{d\mu^k} \mathbb{E} [e^{\tau_{\lambda} \mu}] = \frac{d^k}{d\mu^k} e^{s \beta(\mu)}. \tag{24}
\]

The exponential can be expanded as \( e^{s \beta(\mu)} = 1 + s \beta(\mu) + s^2 f(\mu, s) \), where \( f(\mu, s) = \sum_{j=0}^{\infty} \frac{s^j \beta(\mu)^{j+2}}{(j+2)!} \). Thus, for \( k \geq 0 \), (24) becomes
\[
\mathbb{E} [\tau_{\lambda} e^{\mu \tau}] = \begin{cases} 1 + s \beta(\mu) + O(s^2) & k = 0 \\ \frac{s^k \beta(\mu)}{k!} + O(s^2) & k \geq 1. \end{cases} \tag{25}
\]

Combining (23) and (25) gives the desired expectation:
\[
\mathbb{E} [e^{AT} Y e^{At}] = Y + \sum_{i,j=1}^{q} \sum_{k=0}^{M_i-1} \sum_{l=0}^{M_j-1} t^{k+l} \Gamma_i^k \Gamma_j^l \Gamma_i^l Y \Gamma_j^l + O(s^2).
\]

The expressions for \( G \) and \( H \) can be found by combining the argument above with the scalar formula
\[
\int_0^t \sigma e^{\lambda s} d\sigma = \begin{cases} (e^{\lambda t} - 1) (-1)^{k} k! \lambda^{-k-1} & \lambda \neq 0 \\ e^{\lambda t} \sum_{i=1}^{k} \frac{k^i t^i}{i!} (-1)^{k-i} \lambda^{-k-i-1} & \lambda = 0. \end{cases}
\]

VI. Conclusion

The time-changed regulator problem in this paper could be extended in numerous ways. For instance, time-varying cost matrices could be incorporated by simply changing \( Q \) and \( R \) to \( Q_s \) and \( R_s \), respectively. Coupling in the cost between \( x_s \) and \( u_s \) is also simple. Subtleties may arise in infinite horizon, since it is unclear when (12) tends to a steady-state solution. Generalization to output feedback seems challenging.

Lemma 1 and (12) could likely be explained in terms of Itô’s formula for Lévy processes. Such an interpretation might be helpful in the extension of the dynamic programming argument to nonlinear systems.

Additionally, most of the arguments should extend with minimal change if the system is also driven by a Brownian motion, independent of the time-change. If, however, they are correlated the results could be more difficult. The problem would also be more interesting if the time-change could be correlated with the state and input history.
